Metal Transfer in CO₂-shielded Arc-Welding

S/125/60/000/010/004/015
A161/A133

The proper plate thickness was stated to be 5-6 mm (for a 2 mm electrode wire). It was stated previously (Ref.5) that the change from reversed to straight polarity shortens the arc and reduces the current. In these experiments such a change reduced the current from 400 to 270 amp, and the drop formation and transfer changed. It can be plainly observed on the film that in the case of straight polarity the drop forms on the electrode side surface, and the large drop does not fall and close the arc gap which proves that gas

forces were the cause, but the present experiments have not confirmed it. The axial component was absent in a symmetric arc, and gas streams seemed not to exist, but strong gas streams were observed between two melting electrodes 2 mm in diameter placed horizontally, and it was obvious that the stream from the anode suppressed the stream from the cathode. It may be concluded that electrostatic forces take part in the formation of gas streams. The following conclusions are presented: 1) The current polarity and the welding process conditions affect the nature of metal transfer from the electrode to the workpiece at low currents (200-250 amp) with reversed

6096. THE DAILY RHYTHM OF UROPEPSIN EXCRETION AND THE DIAGNOSTIC VALUE OF ITS 24-HOUR EXCRETION IN SOME PATHOLOGICAL CONDITIONS OF THE GASTROINTESTINAL TRACT - Denní rytmus vylučování uropepsinu a diagnostická cena jeho 24 hodinové exkrece u některých patologických stavů gastrointestinálního traktu - Ronský R. and Skála I. - ČAS. LÉK. ČES. 1958, 97/38 (1202-1208) ~~Graphs & Tables~~

The daily rhythm of uropepsin excretion was followed in 73 patients in 4-hour periods, while the daily excretion was measured in a further 243 patients. Maximum concentration occurs in the period from 6-10 a.m., while the maximum total excretion occurs in the period 2-6 p.m. Minimal concentration and excreted amounts were found from 10 p.m.-2 a.m. The severity of the disease had no effect on this rhythm. The maximum-minimum differences were on the borderline of 95%, so that it is advised to use 24-hour specimens. There was no significant difference in uropepsin excretion between day and night samples. Day-to-day

TITLE: Electrochemical and corrosion behavior of aluminum-base binary alloys and intermetallic compounds

SOURCE: Korroziya metallov i splavov (Corrosion of metals and alloys), no. 2. Moscow, Izd-vo Metallurgiya, 1965, 59-79

TOPIC TAGS: aluminum base alloy. binary alloy. electrochemistry corrosion

L 28405-66

ACC NR: AT6013788

potentials occupy intermediate values with respect to the potentials of the components of binary Al-base alloys. The corrosion behavior of IMC may be markedly affected by the component remaining at the surface in the process of the selective dissolution of the compound. E.g. during the dissolution of FeAl_3 in 0.1N NaOH during the first 40-50 min its potential becomes somewhat displaced in the positive direction while the corrosion rate increases at the same time. This is a consequence of the increase in the cathodic surface area of Fe in the process of the selective dissolution of the IMC. After the potential $E = -0.890-0.920$ v is reached -- which corresponds to the passivation potential of FeAl_3 on polarization curve 2 in Fig. 1 -- there occurs a sharp increase in the potential and decrease in the corrosion rate of this IMC. The anodic reaction with the most negative potential for the

anodic behavior of IMC shows that, from the electrochemical standpoint, the dissolution of such compounds as CuAl_2 or NiAl_2 in the presence of their self-dissolution potentials cannot involve the simultaneous passage of both components into the solution. These findings should contribute to the formulation of a unified theory of the corrosion of alloys which takes into account the special features of the corrosion of solid solutions, eutectics and IMC and their combinations which enter in the structure of any alloy. Orig. art. has: 12 figures and 6 tables.

was 1-15 mV. The electrode potentials of intermetallic compounds have values intermediate between the electrode potentials of the pure metals. The kinetics of dissolution of the intermetallic compounds is a function of the electrochemical properties (anodic and cathodic behavior) of the pure metal constituents. In the region between the self-dissolving potential of the intermetallic compound and the steady-state potential of the cathode component, the anode behavior of the intermetallic compound is a function of the properties of the anodic component. The cathodic properties of the anodic component show up first at very high potential

-0.980 v -- $\text{Fe}_3\text{O}_4 + 4\text{H}_2\text{O} + 8\text{e}^- \rightarrow 3\text{Fe} + 8\text{OH}^-$. The first delay corresponds to the reduction of $\text{Fe}(\text{OH})_3$; the second, to the incomplete reduction of the $\text{Fe}(\text{OH})_2$; and the third, to the reduction of the magnetite Fe_3O_4 , which involves the highest overvoltage and lasts longest. The O_2 dissolved in the electrolyte contributes to the passivation of Fe, chiefly accelerating the cathodic process, and it also exerts a similar effect on the passivation of Cu. The anodic behavior of Cu in the alkali medium at 25°C, characterized by two successively evolving processes of the formation of Cu_2O and CuO directly from Cu, corresponds to a virtually reversible -- in the amount of electricity (the amount of electricity expended on the formation of the Cu_2O (CuOH) film is virtually equal to the amount of electricity expended on its reduction) -- potential delay on the galvanostatic curves with respect to the film.
